REVIEW OF ELECTRICAL QUANTITIES AND BASIC Version Date 08/31/03

CIRCUIT ELEMENTS Free Charge

Most matter is macroscopically electrically neutral most of the time. Exceptions: clouds in thunderstorm, people on carpets in dry weather, plates of a charged capacitor, etc.

Microscopically, of course, matter is full of charges. Consider solids:

- Solids in which all charges are bound to atoms are called insulators.
- Solids in which outer-most atomic electrons are free to move around are called *metals*.
 - Metals typically have ~ 1 "free electron" per atom (~ 5 X10²²/cm³)
 - C stands for the units of charge called Coulomb
- Semiconductors are insulators in which electrons are not tightly bound and thus can be easily "promoted" to a free state (by heat or even by "doping" with a foreign atom).

Al or Cu – good great for wires Si or GaAs –

POSSIBLE CONCEPTUAL ISSUES

Version Date 08/31/03

1 How does charge move through the wire?

Remember a wire has a huge number of free carriers moving very fast but randomly (because of thermal energy)

Drift concept: Now add even a modest electric field

Carriers "feel" an electric field along the wire and tend to drift with it (+ sign charge) or against it (– charge carrier). This drift is still small compared to the random motion.

2 Sign of the charge carriers: It is often negative (for metals); in silicon, it can be either negative or positive.

> Ben Franklin: Picked/guessed that carriers in wires have a positive sign and move with the electric field. In fact electrons have a negative charge and go the other way (in a positive field). But of course the current is the same for either + or - Q since they move in opposite directions in a given field.

CHARGE (cont.)

Version Date 08/31/03

Charge flow → Current

Charge storage → Energy, information

Definition of current i (or I)

i (in Amperes) = flow of 1 coulomb per second

where \mathbf{q} is the charge in coulomb and t is the $i(A) = \frac{dq}{c}$ where **q** is time in sec

Note: Current has sign

Examples:

(a)

 10^5 positive unit charges of value $e=1.6\times10^{-19}C$ flow to right (+ x direction) every nanosecond

 $i - \frac{10^5 \times 1.6 \times 10^{-19}}{10^5 \times 1.6 \times 10^{-19}} = 1.6 \times 10^{-5} A = 16 \mu A \text{ (left to right)}$

(b)

10¹⁰ electrons flow to right in a wire every microsecond $i = \frac{-10^{10} \times 1.6 \times 10^{-19}}{-1.6 \times 10^{-3}} = -1.6 \text{mA}$ (left to right)

EE 42 Intro. Digital Electronics Fall 2003

Lecture 2: 08/28/03 A.R. Neureuther

POSSIBLE CONCEPTUAL ISSUES (con't)

3. Modern Definition re signs: Electric field is in the direction positive charge carriers move. Thus if we have an electrical field in the Z direction, positive charges (ions, positrons, whatever) will experience a force in the positive ${\sf Z}$ direction. Negatively charged particles will experience the force in the -Z direction.

Thus the free carriers we will be concerned with (electrons with negative charge and "holes" with positive charge) will move against and with the electric field respectively.

4. Field or Current can have positive or negative sign.

Examples: I = 0.2 mAsame as

I = -0.2 mA(Think about hooking up an ammeter and then reversing its connection. The sign of the current it reads must change.)

EE 42 Intro. Digital Electronics Fall 2003

Lecture 2: 08/28/03 A.R. Neureuther

Version Date 08/31/03

POSSIBLE CONCEPTUAL ISSUES (con't)

5. When we have unknown quantities such as current or voltage, we of course do not know the sign. A question like "Find the current in the wire" is always accompanied by a definition of the direction:

(or)

In this example if the current turned out to be 1mA, but flowing to the left we would merely say I = -1mA.

6. Thus there is no need to guess the reference direction so that the answer comes out positive....Your guess won't affect what the charge carriers are doing! Of course you will find that your intuition and experience will often guide you to define a current direction so that the answer comes out positive.

KEEPING THE VOLTAGE SIGNS STRAIGHT

Labeling Conventions

- Indicate + and terminals clearly; or label terminals with letters
- The + sign corresponds to the first subscript; the sign to the second subscript. Therefore, V_{ab} = - V_{ba}

Note: The labeling convention has nothing to do with whether or not v > 0or v < 0

Using sign conventions:

$$V_{ab} = 1$$
; $V_{ca} = -2$, thus
 $V_{cb} = -2 + 1 = -1 V$

Obviously $V_{cd} + V_{db} = V_{cb}$ too. Then if $V_{bd} = 5V$, what is V_{cd} ?

Lecture 2: 08/28/03 A.R. Neureuthe

Version Date 08/31/03

THINKING ABOUT VOLTAGE ("electrical potential")

Definition: Voltage (electrical potential) is the electrical energy per unit positive charge. The Units are Volts = Joules/Coulomb

"Vab" means the potential at a minus the potential at b.

Generalized circuit element with two terminals (wires) a and b, with a potential difference across the element

Potential is always referenced to some point ($_{_{\rm V}}$ $\,$ in the example; $_{_{_{\rm V}}}$ $\,$ is measured with respect to V_h) Sign Convention

EE 42 Intro. Digital Electronics Fall 2003

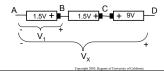

Version Date 08/31/03

SIGN CONVENTIONS (cont.)

Normally we do not need two subscripts for voltages because:

- 1) We have defined a point in the circuit to the reference node (common or "ground"), I.e. the place where we will atttach the common wire of the voltmeter. Thus all voltages are measured OR with respect to this point.
- 2) We use "brackets" with signs to indicate the polarity and symbol:

How are single-subscript voltages related to double-subscript voltages?

EE 42 Intro. Digital Electronics Fall 2003

Lecture 2: 08/28/03 A.R. Neureuther

Version Date 08/31/03

SIGN CONVENTIONS (cont.)

Lets put a bunch of batteries, say 1.5V and 9V in series to see what we already know about sign conventions:

Example 1

 $V_{AB} = -1.5V$

 $V_{BC} = -1.5V$

What is VAD?

Math Approach: Factor into known steps

$$V_{AD} = V_{AB} + V_{BC} + V_{CD} = (+1.5) + (+1.5) \cdot 9V = (+6)$$

Physical Approach: Add the voltage (potential) drops $V_{AD} = (1.5) + (1.5) + (-9) = -6$

EXAMPLE OF SINGLE-SUBSCRIPT NODE VOLTAGES

Choose a reference (ground) and define the circuit voltages with respect to this point. This is equivalent to attaching common node of voltmeter to the reference node.

Thus we can connect the + lead of the DVM to point (Node) A and call the potential of point A "VA", similarly at points (Nodes) B, C

Of course what V_A means is the potential of point (Node) A with respect the point connected to the common lead of the DVM. What is V_A?
