| Lecture 26: Global Optimization | | Topics | |
|---|---|---|--|
| [Adapted from notes by R. Bodik and G. Necula] | | Global optimization refers to program optimizations that encompass multiple basic blocks in a function. | |
| | | (I have used the term <i>galactic optimization</i> to refer to going beyond function boundaries, but it hasn't caught on; we call it just <i>interpro-</i> <i>cedural optimization</i>.) | |
| | | Since we can't use the usual assumption optimization requires global flow and come from and get used. | tions about basic blocks, global <i>alysis</i> to see where values can |
| | | • The overall question is: When can local optimizations (from the last lecture) be applied across multiple basic blocks? | |
| | | | |

| Example: Clobal Constant | Pronocation | Example of Degult of Com | stant Propagation |

Example: Global Constant Propagation

- *Global constant propagation* is just the restriction of copy propagation to constants.
- In this example, we'll consider doing it for a single variable (X).
- \bullet At every program point (i.e., before or after any instruction), we associate one of the following values with ${\tt X}$

| Value | Interpretation |
|-------|--|
| # | (aka <i>bottom</i>) No value has reached here (yet) |
| с | (For c a constant) X definitely has the value c . |
| * | (aka <i>top</i>) Don't know what, if any, constant value X has. |

Example of Result of Constant Propagation

Using Analysis Results

- Given global constant information, it is easy to perform the optimization:
 - If the point immediately before a statement using x tells us that x = c, then replace x with c.
 - Otherwise, leave it alone (the conservative option).
- But how do we compute these properties x = ...?

Transfer Functions

- Basic Idea: Express the analysis of a complicated program as a combination of simple rules relating the change in information between adjacent statements
- That is, we "*push"* or *transfer* information from one statement to the next.
- For each statement s, we end up with information about the value of x immediately before and after s:

Cin(X,s) = value of x before s Cout(X,s) = value of x after s

- Here, the "values of x" we use come from an abstract domain, containing the values we care about—#, *, k—values computed statically by our analysis.
- For the constant propagation problem, we'll compute Cout from Cin, and we'll get Cin from the Couts of predecessor statements, Cout(X, p_1),...,Cout(X, p_n).

If $Cout(X, p_i) = *$ for some i, then Cin(X, s) = *

If Cout(X, p_i) = c and Cout(X, p_j) = d with constants $c \neq d$, then Cin(X, s) = *

An Example of the Algorithm

So we can replace X with 3 in the bottom block.

Another Example of the Propagation Algorithm

Here, we cannot replace X in two of the basic blocks.

CS164: Lecture #26 22

- The examples used a depth-first approach to considering possible places to apply the rules, starting from the entry point.
- In fact, the order in which one looks at statements is irrelevant. We could have changed the Cout values after the assignments to X
- The # value is necessary to avoid deciding on a final value too soon. In effect, it allows us to tentatively propogate constant values through before finding out what happens in paths we haven't looked at yet.

Likewise, we cannot replace X.

Ordering the Abstract Domain

- \bullet We can simplify the presentation of the analysis by ordering the values # < c < *.
- Or pictorially, with lower meaning less than,

- ... a mathematical structure known as a *lattice*.
- With this, our rule for computing Cin is simply a least upper bound: Cin(x, s) = lub { Cout(x, p) such that p is a predecessor of s }.

CS164: Lecture #26 25

Liveness Analysis

Once constants have been globally propagated, we would like to eliminate dead code

After constant propagation, X $\,:=\,3$ is dead code (assuming this is the entire CFG)

Termination

- Simply saying "repeat until nothing changes" doesn't guarantee that eventually nothing changes.
- But the use of lub explains why the algorithm terminates:
 - Values start as # and only increase
 - By the structure of the lattice, therefore, each value can only change twice.
- Thus the algorithm is linear in program size. The number of steps
 - = $2\times$ Number of Cin and Cout values computed
 - = $4 \times$ Number of program statements.

CS164: Lecture #26 26

Terminology: Live and Dead

• In the program

X := 3; /*(1)*/ X = 4; /*(2)*/ Y := X /*(3)*/

- the variable X is *dead* (never used) at point (1), *live* at point (2), and may or may not be live at point (3), depending on the rest of the program.
- \bullet More generally, a variable x is live at statement s if
 - There exists a statement \mathbf{s} ' that uses \mathbf{x} ;
 - There is a path from ${\bf s}$ to ${\bf s}$ '; and
 - That path has no intervening assignment to ${\bf x}$
- A statement $x := \dots$ is dead code (and may be deleted) if x is dead after the assignment.

Computing Liveness

- We can express liveness as a function of information transferred between adjacent statements, just as in copy propagation
- Liveness is simpler than constant propagation, since it is a boolean property (true or false).
- That is, the lattice has two values, with false<true.
- It also differs in that liveness depends on what comes after a statement, not before-we propagate information backwards through the flow graph, from Lout (liveness information at the end of a statment) to Lin.

Liveness Rule 2

...:=X

L(X) = true L(X) = ?

X, such as tests (e.g., X < 0).

| SSA and Global Analysis | ϕ Functions | | |
|---|---|-----------------------|--|
| • For local optimizations, the single static assignment (SSA) form was | • An artificial device to allow SSA notation in CFGs. | | |
| useful. | In a basic block, each variable is associated with one definition, | | |
| But applying it to a full CFG is requires a frick. E.g., how do we avoid two assignments to the temporary holding x | φ functions in effect associate each variable with a set of possible definitions. In general, one tries to introduce them in strategic places so as to minimize the total number of φs. Although this device increases number of assignments in IL, register allocation can remove many by assigning related IL registers to the same real register. Their use enables us to extend such optimizations as CSE elimination in basic blocks to Global CSE Elimination. | | |
| if a > b: | | | |
| <pre>x = a else: x = b # where is x at this point?</pre> | | | |
| • Answer: a small kludge known as ϕ "functions" | | | |
| Turn the previous example into this: if a > b: x1 = a else: x2 = b | • With SSA form, easy to tell (conservatively) if two IL assignments compute the same value: just see if they have the same right-hand side. The same variables indicate the same values. | | |
| $x3 = \phi(x1, x2)$ | | | |

| Summary | | | |
| • We've seen two kinds of analysis: | | | |
| Constant propagation is a <i>forward analysis</i>: information is pushed from inputs to outputs. | | | |
| Liveness is a backwards analysis: information is pushed from out- puts back towards inputs. | | | |
| But both make use of essentially the same algorithm. | | | |
| Numerous other analyses fall into these categories, and allow us to use a similar formulation: | | | |
| An abstract domain (abstract relative to actual values); Local rules relating information between consecutive program points around a single statement; and Lattice operations like least upper bound (or <i>join</i>) or greatest lower bound (or <i>meet</i>) to relate inputs and outputs of adjoining statements. | | | |
| | | | |
